ABSTRACT

Reactor Accelerator Coupling Experiments: A Feasibility Study. (May 2005)

Taraknath Woddi Venkat Krishna, B. Tech.,

Orissa University of Agriculture and Technology

Chair of Advisory Committee: Dr. William S. Charlton

The Reactor Accelerator Coupling Experiments (RACE) are a set of neutron source driven subcritical experiments under temperature feedback conditions. These experiments will involve coupling an accelerator driven neutron source to a TRIGA reactor system in a subcritical configuration. The accelerator source will consist of a 40 MeV electron linear accelerator (LINAC) and a heavy metal target. The electrons from the accelerator produce bremsstrahlung radiation in the target which in turn produces a source of neutrons via photonuclear reactions. The available core at the The University of Texas at Austin (UT) with standard TRIGA fuel will be used to carry out these studies.

The primary objective of this thesis was to study the feasibility of RACE especially with respect to the heat generation rates capable of placing the reactor in a temperature feedback regime. First, the accelerator target (or neutron source) was optimized for size, shape, and type of material to be used. Analyses were then performed for several arrangements of this target in the UT TRIGA reactor. One of these arrangements was found to provide heat generation rates well into the temperature feedback regime of the fuel. Lastly, a multi-target system [named the Texas

Transmutation System (TTS)] was designed to allow for more detailed accelerator driven systems (ADS) studies. It was shown that this system would allow for operation over a wide-range of subcriticalities and with a wide-range of heat loads. Thus, the feasibility for these experiments has been proven, and it is recommended that continued study and implementation of these experiments be performed.

ACKNOWLEDGEMENTS

This thesis would not have been possible without Dr. William Charlton giving me the opportunity to work on his project. It was because of his faith and support that I could reach a point to where my contribution to the efforts of ADS has been acknowledged.

I convey my sincere gratitude to all my committee members: Dr. Marvin Adams, Dr. Ronald Ellis and Dr. Rabi Mahapatra for sparing their precious time and giving me useful suggestions.

I would take this opportunity to thank Dr. Hart, Dr. Reece and Dr. Ragusa for creating an academic acumen in me and for providing the required technical skill set to attain the goals of this research.

No honors are complete without the blessings and help of family and friends. My mom (Basanti), my dad (Pattabhiram), my wife (Divya), my sister (Jeanie) and brother in law (Tanuj) were the pillars of confidence during hard times. My friends Julien Partouche, David Oertli, David Burk, Kaydee Kohlhepp and Alexander Pasciak were the spring board for getting me over the research hurdles.

I. INTRODUCTION

The quantity of spent fuel discharged from U.S. nuclear reactors will reach 87,000 tons by the time the existing U.S. nuclear plants reach the end of their license period. This discharged fuel contains 95% uranium (comparable to natural uranium), about 1-2% transuranic elements (principally plutonium), and 3% fission products and activation elements. Most fission products decay to stable nuclides within a few decades; however, a small number of nuclides (^{99}Tc and ^{129}I , for example) remain radioactive for many thousands of years and contribute to long-term repository waste management requirements. The amount of plutonium existing today is approximately 600 tons, and at the end of the license period for the current U.S. fleet of reactors it will reach 870 tons. The inventory of ^{99}Tc and ^{129}I will be 78.3 tons [1].

The radiotoxicity of spent nuclear fuel remains at a level above that of natural uranium for 200,000 years after discharge from a typical light water reactor [2]. The majority of the long-term radiotoxicity of spent nuclear fuel is due to the transuranic radionuclides. If both plutonium and americium are completely transmuted to stable or shorter-lived nuclides, the required lifetime of a geological repository can be drastically reduced. This transmutation can be performed via fission. The fission process would result in the generation of generally shorter-lived fission products and would produce useable energy.

This thesis follows the style of *Nuclear Technology*.

Current fast reactor designs would be able to transmute the plutonium via fission with a reasonable degree of efficiency; however, from a safety perspective, limits on the allowable concentration of minor actinides (i.e, neptunium, americium, and curium) in fissile fuel for critical reactor systems is about 5%. This is due primarily to the lower delayed neutron fraction and Doppler reactivity coefficient effects from these nuclides. Taking into account the large inventory of americium arising from the decay of ^{241}Pu presently being stored, it is of primary necessity that realistic transmuters for burning these minor actinides are developed. It has also been shown that critical fast reactor systems are not capable of transmuting the fission product waste from spent nuclear fuel [3]. This is due to the criticality limitation on neutron conservation in the system (i.e., one neutron from each fission chain must cause another fission to continue the self-sustaining chain reaction). There simply are not enough neutrons per fission available in a critical fast reactor to transmute plutonium, minor actinides, and fission products.

One system which may be capable of transmuting the plutonium, minor actinides, and fission product constituents of spent nuclear fuel is an accelerator driven system (ADS). An ADS consists of a subcritical array of fuel driven by an accelerator produced neutron source. Since the system is subcritical, there is no criticality limitation on the neutrons in the fission chain. Thus, if needed every neutron from the source per fission could be used to transmute materials.

The state of ADS research has advanced considerably in the last 15 years. A variety of ADS designs have been studied in the past [3-7], and a number of accelerator

driven neutron sources have been designed and built over the years (including fusion sources using D-T fusion, spallation neutron sources using a proton beam, and photoneutron sources using an electron accelerator). However, an ADS system of significant power has never been built and operated. The knowledge base relating the operational characteristics of these systems is virtually non-existent.

ADS has been studied for use in transmutation of nuclear waste, production of energy, tritium production, and incineration of weapons grade plutonium; however, the experimental research in this field is sparse. This is at least in part due to the high costs associated with most high-energy particle accelerators. In this regard, experimental research with ADS on the basis of lower energy accelerators is of great importance and could provide valuable prototyping data.

This thesis describes a set of experiments, named the Reactor Accelerator Coupled Experiments (RACE), which are being planned in Texas and will provide operational data for ADS operated at significant power levels and with reactivity feedback. These experiments will involve coupling an accelerator driven neutron source to a TRIGA reactor system in a subcritical configuration. The accelerator source will consist of an electron linear accelerator (LINAC) and a heavy metal target. The electrons from the accelerator produce Bremsstrahlung radiation in the target which in turn produces a source of neutrons via photonuclear reactions. Of principle interest in these experiments is to operate at a power level which would allow for observation of thermal feedback effects on the subcritical system (generally above 1-kW). In this work, the

feasibility of these experiments was studied especially with respect to the capability of the system to allow for operation in the thermal feedback regime of a TRIGA reactor.

I.A. RACE Overview

Both the University of Texas at Austin (UT) and Texas A & M University (TAMU) operate 1-MW TRIGA research reactors. These reactor systems use TRIGA reactor fuel which has been shown to have exceptional safety characteristics even under the most extreme transients. The RACE experiments will couple the accelerator source to these TRIGA reactors to study the operational characteristics of these ADS. The source of neutrons is expected to have strength on the order of 1×10^{13} n/s. These experiments are expected to allow for study of the following:

1. Behavior of an ADS at power levels between 1-20 kW and at various levels of subcriticality (ranging from $k_{eff}=0.90$ to $k_{eff}=0.99$)
2. Methods for level of subcriticality measurement at significant powers.
3. Reactivity control by various means including via neutron source importance variation.
4. Compensation of reactivity feedback with control rod adjustment or by altering the accelerator current.

The RACE project has four principle goals:

1. Produce an ADS demonstration with adjustable reactivity to demonstrate the ability to design, compute, and conduct ADS experiments and benchmark the ability to predict and analyze subcritical source-driven transients.

2. Provide ADS benchmark data for developing codes and methods for analyzing static and transient behavior.
3. Produce a teaching tool that can be used to educate the next generation of scientists and engineers in the operation and modeling of ADS and in advanced nuclear science.
4. Advance the state of knowledge of ADS transmutation

A neutron source will be built and tested at Idaho State University for this project. This neutron source will be coupled to the UT Nuclear Engineering Teaching Laboratory (NETL) 1-MW TRIGA Mark II research reactor to study static and transient operation characteristics.

After completion of the experiments at UT, the accelerator driven source will be moved to the Nuclear Science Center (NSC) at TAMU. A subcritical assembly composed of spent fuel discharged from the TAMU NSC TRIGA reactor will be designed and built for location in the NSC pool. The accelerator driven source will be inserted into the reactor and used to evaluate static and transient effects with the source in several internal locations in the core and with adjustable reactivities up to k_{eff} of 0.98.

I.B. Theory

As envisaged, ADS is a promising new concept for transmutation of long-lived nuclides from spent nuclear fuel. The principal system under study is the proton accelerator driven ADS. These proton accelerators are generally large scale facilities requiring large capital and operating costs. The RACE program will make use of a

smaller scale system with an electron LINAC driven neutron source. There are several advantages in using an electron beam rather than a proton beam including:

1. Electron accelerators are small and compact machines
2. Less costly to build and operate,
3. More dependable and safer to operate and
4. Considerably lower activation compared to proton machines.

The primary disadvantage is that the electron LINAC will produce much smaller neutron source strengths.

There are three main components of an ADS. These are: (1) a high-intensity accelerator, (2) an accelerator target which will produce neutrons, and (3) a transmuter (that is, a sub-critical reactor-like system containing the material to be transmuted). For the purposes of this work, we will neglect the development of the accelerator and assume that it will be provided. This thesis will focus on the target and transmuter.

When a particle beam from an accelerator hits a thick target of heavy elements (e.g., lead, tungsten, uranium, etc.), a large number of neutrons are obtained. In the case of a proton accelerator, these neutrons are produced via spallation reactions [8]. In the case of an electron accelerator, the electrons are slowed down in the target and emit Bremsstrahlung radiation. These high energy photons then lead to photoneutron reactions in the target. In both cases, most of the charged particles are slowed down and stopped inside the target or in its immediate vicinity due to the Coulomb interaction. The

neutrons however penetrate to the outer surface of the target and reach the surrounding subcritical core.

The external neutrons supplied by photoneutron reactions in the target sustain a constant power in the ADS via subcritical multiplication. The neutrons born in the target have energies ranging from “usual” fission energies (about 1 MeV) up to the energy of the incident charged particles from the accelerator. The neutrons born in the fuel have energies around 1 MeV. The total power in this system can then be adjusted by raising or lowering the current of the accelerator. The power in the ADS is directly dependent upon the power from the accelerator. If the accelerator power is removed, the ADS will shutdown (aside from any decay heat effects). Thus, under normal operating conditions, the ADS have inherent safety from transient effects. Transients in the system which do not increase criticality above $k_{eff}=1$ will always result in a linear response by the ADS (as opposed to an exponential response by a critical system). These inherent safety features make ADS an excellent option when transmuting actinides with lower delayed neutron fractions (like plutonium and americium).

I.C. Previous Work

I.C.1. Background

The first significant investigation of using a spallation system for high-level waste transmutation was the APEX project conducted at Brookhaven National Laboratory [9]. The design concept application was to transmute ^{90}Sr and ^{137}Cs , dominate long-lived fission products of reactor spent fuel. The system consisted of a

1500 MeV proton accelerator operating at 300 mA impinging upon a flowing liquid lead target with a blanket of fertile material surrounding the target. The study concluded that the radioactivity of the spent fuel could be reduced by a factor of ten. The disadvantage of this study was there were no technical specifications provided for the target dimensions and operation of the flowing lead system.

Another study to transmute actinides of reactor spent fuel was conducted by Nishida *et al.* [10]. The design concept was a 1500 MeV, 7.8 mA accelerator using a transuranic target with a liquid lead-bismuth eutectic (LBE) coolant to transmute actinide alloys. The disadvantage of this system is that the transuranic target produces long-lived radionuclides in addition to those being transmuted.

The most detailed and comprehensive research conducted for accelerator-based waste transmutation began in 1992 by Los Alamos National Laboratory [11]. This included analysis of structural activation of accelerator components, target/blanket designs, liquid metal corrosion issues, and radiation damage of target and structural components [12-16]. The majority of these studies were computational in nature.

Several studies have occurred outside the U.S. as well. Detailed work was performed as part of the Japanese Omega program which was started in 1988 [17]. Studies of ADS at KTH started in 1993 [18]. Shortly after this, the CERN proposal of thorium-fueled ADS attracted a lot of attention in international media [19]. While various concepts have been suggested, the attention of the detailed design work in Japan,

Korea, the United States and Europe is now firmly focused on fast neutron spectrum, solid fuelled cores being supplied with source neutrons from a spallation neutron source.

I.C.2. Muse Experiments

Since 1997, the hybrid reactor group from Grenoble has been involved in an experimental program called MUSE (MUltiplication de Source Externe) in collaboration with the French CEA (Commissariat à l'Énergie Atomique), EDF (Electricité de France), and FRAMATOME. This experimental program takes place at the research reactor MASURCA (MAquette de SURgénérateur à CAdarache) of the CEA Nuclear Center of Cadarache. It is devoted to the study of neutronics in a fast sub-critical core subjected to an external neutron source. MUSE also studies the validation of correlated calculation codes. The measurements done during these experiments served as a test for the characterization of the neutron flux in a sub-critical medium, driven by an external source [20].

Dynamic experiments were carried out by operating the reactor in a sub-critical mode with a $k_{eff}=0.86$ and with a D-T neutron source (yield of 3×10^4 neutrons/pulse). The preliminary results were encouraging. The results have shown that there is a non-global response of the sub-critical block to a neutron pulse, the response depends both on local flux and energy spectrum. This data is very valuable for understanding the kinetics of the sub-critical media.

I.C.3. TRADE Experiments

TRADE (TRiga Accelerator Driven Experiments) was the result of collective effort of a working group composed by ENEA, CEA, CERN ANSALDO under Carlo Rubbia (ENEA) and Massimo Salvatores (CEA). The TRADE experiment was to be performed in the TRIGA reactor of the ENEA Cassaccia Center and consists of the coupling of an external proton accelerator to a target to be installed in the central thimble of the reactor with the reactor placed in a subcritical configuration. The pilot experiment was aimed at global demonstration of the ADS concept [21]. The TRADE experiments however have been recently abandoned by the ENEA due to high costs.

I.D. Project Overview

The next section of this thesis will describe the accelerator driven neutron source target design and analysis. Following that section, analysis of the use of that source in the UT NETL reactor will be given with special emphasis on the heat generation rates capable in the system with an electron LINAC source. Section IV details the design of a spent fuel experiment at TAMU using the neutron source design from Section II and again with special emphasis on heat generation rates.

II. ACCELERATOR DRIVEN NEUTRON SOURCE DESIGN

An accelerator driven neutron source for use in the RACE experiments was designed. Coupled electron-photon-neutron simulations were performed using MCNP-5 [22]. The target optimization was performed to optimize the neutron leakage from the target.

There are several parameters which influence the neutron production and leakage of the neutrons produced. These include:

1. Type of incident particle,
2. Energy of incident particle,
3. Location and size of beam on target,
4. Target geometry (cylindrical, hexagonal, conical, etc.),
5. Target material, and
6. Target dimensions.

In all cases, it was assumed that the electron LINAC produced electrons of 40 MeV in energy and with a beam spot of 1.0 cm in diameter. It was also assumed that all targets would be cylindrical in geometry due to simplicity of design and construction. Since it was assumed that the first four of these parameters were fixed, target optimization was performed by varying the target materials and dimensions. Three source materials were considered: lead, tungsten, and a tungsten-copper alloy. These target materials were then optimized for target radius and length using bare target calculations. MCNP input decks for the optimized targets can be found in Appendix A.

II.A. Lead Target Optimization

The length and radius of this target was varied to determine the optimal target dimensions. The radius was varied from a radius of ~ 1.5 cm to a radius of ~ 10.0 cm. The outgoing neutron current from the source versus target radius as calculated by MCNP-5 is shown in Fig. 1. As can be seen from Fig. 1, an optimal target radius exists at ~ 5.5 cm. The target length was then varied from ~ 5 cm to ~ 40 cm and the results are shown in Fig. 2. These simulations showed that there was no significant increase in exiting neutron current at target lengths greater than 10 cm. The optimal target dimensions were calculated to be 5.4 cm in radius and 25.0 cm in length. These dimensions are also sufficiently small to allow the target to easily fit into the space available in the reactors.

Fig. 1. Exiting neutron current versus target radius for lead target.

Fig. 2. Exiting neutron current versus target length for lead target.

It should be noted that the choice of lead as a target material is only for the purpose of this feasibility and scoping study. Since lead has such a low melting point, it is advantageous in RACE to use a tungsten (or tungsten alloy) target instead of a lead target. Past studies have focused heavily on lead and lead-bismuth targets. Thus, lead was included here to allow for easier comparisons to other works.

II.A.1. MCNP Parameter Optimization

In the process of the target dimension optimization, the *phys* cards in MCNP were also optimized. These cards are integral deciding factors for the computational time

and solution mechanisms used by MCNP for they determine the detail with which MCNP treats photon and electron interaction physics. These cards were optimized to provide the most detailed physics possible and to minimize computational time without effecting the neutron production.

The *phys* card optimizations were performed by iterating on the parameters used on each card. The following is the optimized *phys* cards for photons and electrons:

```
phys:p 1000 0 0 1 0
```

```
phys:e 50 0 0 0 0 10 1 0 1 0
```

The upper limit for electrons has been set as 50 MeV. This number is sufficient for these simulations since the incident electron beam is only 40 MeV. It was figured out that knock on electrons do not have any contribution in production of source neutrons and energy reduction of electron after collision has to be considered in continuous spectrum rather than predicting its probability. Higher production of neutrons per electron is obtained if electron-photon simulation is carried out with full bremsstrahlung angular distribution. However this switches off the photons striking the detector. This is the desired effect if we set fast detectors with gamma compensation. Doppler broadening and secondary electron contribution are significant. The reader is referred to the MCNP-5 manual for more information about these cards [22]. The *phys:p* card results in the following characteristics for the simulation:

1. upper limit for photons 1000 MeV
2. photons do produce electrons

3. coherent scattering occurs
4. biased photonuclear collision sampling
5. Doppler energy broadening occurs

The *phys:e* card results in the following characteristics for the simulation:

1. upper limit for electrons 50 MeV
2. photons will not produce electrons
3. electrons will produce photons
4. full bremsstrahlung tabular angular distribution
5. sampled straggling for electron energy loss
6. 10 times of bremsstrahlung photons production
7. x-ray photons produced by electrons
8. knock-on electrons will not be produced
9. photon induced secondary electrons produced
10. nominal bremsstrahlung production

II.B. Tungsten Target Optimization

Similar to the lead source optimization, the radius and length of the tungsten target was varied and the exiting current from MCNP-5 was recorded. Tungsten produced more neutrons for a smaller radius than that of the lead target. The *phys* cards used were same as those used for the lead target. Plots of the exiting current versus radius and versus length are shown in Figs. 3 and 4, respectively. The optimized radius was found to be 3.0 cm with the length remaining at 25 cm.

Fig. 3. Exiting neutron current versus target radius for tungsten target.

Fig. 4. Exiting neutron current versus target length for tungsten target.

It was interesting to note that as the radius was increased beyond the optimum value, the neutron production did not decrease by a substantial amount. This yielded the flexibility of using a bigger radius target, if desired, without resulting in a loss of neutron production. Also, we should note that the tungsten target produced nearly 15% more neutrons for the optimized radius when compared to the lead target.

Fig. 5. Exiting neutron current versus target radius for W-Cu target.

II.C. Tungsten-Copper Alloy Target Optimization

The third kind of material considered was an alloy of tungsten. It consisted of 70% by weight tungsten and 30% by weight copper. The optimization was again performed by varying the radius and length of the target and recording the exiting neutron current (Figs. 5 and 6). The optimized radius was found to be 3.2 cm and 25 cm in length. It was noted that the inclusion of the copper has little effect on the neutron production; however, it makes the tungsten much easier to machine and braze.

Fig. 6. Exiting neutron current versus target length for W-Cu target.

II.D. Target Cooling

There are two locations where the target can be inserted into the reactor. One location is in a beam port the other is inside the central area of the core. If the target is in the beam port, then there will be little to no cooling available from the air space in the beam port. In the beam port, there is no coolant for cooling the target. Thus, a cooling jacket was designed that would flow chill water around the target at a rate of 1.9 liters/min. This rate is sufficient for removing the heat generated in the target (up to 20 kW) using facility chill water at UT. The target with the cooling jacket is shown in Fig. 7.

Fig. 7. Target with cooling jacket.

In case of the target being set inside the core, the cooling jacket is not required, since the pool water will provide cooling. This also implies that more heat can be added freely to the target (up to the limitations of the core cooling system).

III. ANALYSIS OF EXPERIMENTS USING UT NETL TRIGA REACTOR

III.A. Description of UT NETL

The UT Nuclear Engineering Teaching Laboratory (UT-NETL) houses a 1-MW TRIGA MARK-II nuclear research reactor. This reactor can be operated in two modes: pulse and steady-state. Safety analysis demonstrates that safe operation at power levels as high as 1.5-MW steady-state and 8400-MW peak pulse power is feasible. Pulse mode operation takes place by step reactivity insertions with reactor power initially at a power level of less than 1 kW. The maximum step reactivity insertion of 2.2% $\delta k/k$ (\$3.14) will produce a peak reactor power of approximately 1700 MW with a prompt energy release of 21 MW-sec. The safety of the TRIGA fuel arises from a large, prompt negative temperature coefficient that is characteristic of U-ZrH fuel moderator elements used in TRIGA systems. As the fuel temperature increases, temperature coefficient immediately compensates for reactivity insertions. The result is that reactor power excursions are terminated quickly and safely. The primary design characteristics for the UT-NETL reactor are given in Table I. A schematic of the core layout is shown in Fig. 8.

TABLE I
Principal Design Characteristics of the UT-NETL Reactor

REACTOR TYPE	TRIGA MARK – II
STEADY-STATE POWER (MAXIMUM)	1.1 MW (1.5 MW DESIGN)
PULSE POWER (MAXIMUM)	2.2 % $\delta k/k$ (\$3.14)
FUEL ELEMENT DESIGN	
FUEL – MODERATOR MATERIAL	U-ZrH
H/Zr RATIO	1.6 (1.65 MAXIMUM)
URANIUM CONTENT	8.5 WT %
URANIUM ENRICHMENT	19.7% U -235
SHAPE	CYLINDRICAL
LENGTH OF FUEL	38 CM
DIAMETER OF FUEL	3.63 CM
CLADDING MATERIAL	304 STAINLESS STEEL
CLADDING THICKNESS	0.051 CM
NUMBER OF FUEL ELEMENTS	
CRITICAL CORE	~ 64
OPERATIONAL CORE	~ 90
EXCESS REACTIVITY (MAXIMUM)	4.9 % $\delta k/k$

III.B. Analysis of Experimental Arrangements at UT NETL

The target designed in Section II will be inserted into the UT NETL core, coupled with a 40 MeV electron LINAC (operating at 4-kW of beam power), and used to drive the core in a subcritical configuration. Two core locations were proposed for the target: one in beam port #5 (a tangential through tube port, Fig. 8) and the other in the core central thimble. Irradiation in the beam port would allow for a relatively simple test (i.e., requiring no fuel movement) at low power. The target in the central thimble will allow for the highest possible heat generation and is most relevant to proposed ADS operation. Four experimental cases were analyzed to determine the feasibility of these experiments. These cases are as follows:

1. Target located in beam port #5 (BP#5).
2. Target located in core central thimble.

3. Target located in core central thimble and control rods moved out one ring.
4. Target located in core central thimble and control rods moved out two rings.

A full core MCNP model for the UT NETL reactor was constructed. This model explicitly simulated all fuel rods, control rods, graphite rods, graphite reflector, beam ports, and pool water. The physical domain of the model ended at the pool wall. Each case was simulated in MCNP and the heat generation rate in the fuel was recorded. For the purposes of observing thermal feedback effects, heat generation rates above 1 kW were desired. Simulations were performed for all three optimized target materials (i.e., lead, tungsten, and tungsten-copper). The results for each case are reported in the following sections.

III.B.1. Core Arrangement #1

In this arrangement, the target was placed in BP#5 as close to the fuel as possible. The target had a cooling jacket in place for heat removal. The target had a radius of 5.0 cm. The cladding on the target was 0.5 cm thick, the cooling gap was 0.4 cm thick, and the outer jacket was 0.5 cm thick. The electron beam entered the target from the BP#5 side. A thin beryllium window (0.001 cm thick) faced the electron beam (as per the optimized target shown in Fig. 7). A schematic of the target in position in BP#5 is shown in Fig. 9. The MCNP-5 calculated heat generation rate in the fuel for this arrangement using the lead target is shown in Table II. Varying levels of subcriticality were simulated by modifying the control rod heights in MCNP until a k_{eff} of 0.95, 0.98, and 0.99 were achieved.

Fig. 9. Screen capture of MCNP geometry for UT–NETL experiment with accelerator source in beam port # 5.

TABLE II
Heat Generation Rate for Lead Target in BP#5

k_{eff}	Heat Generation Rate (kW)
0.9502 +/- 0.0007	0.58 +/- 0.055
0.9800 +/- 0.0004	0.735 +/- 0.075
0.9901 +/- 0.0004	1.22 +/- 0.145

For safety purposes, k_{eff} will not be allowed to exceed 0.99. At that level of subcriticality, the heat generation rate is approximately 1.2 kW. The primary reason for this low value is that only 1/3rd of the neutrons emitted from target are entering the fuel region. Many neutrons are leaking from the core. This is because the neutrons in the target are emitted isotropically and since only 120 degrees of the target is facing the fuel. Though 1.2 kW is within the range of interest for these experiments, it leaves little chance for error and little opportunity to operate the system at lower k_{eff} values.

The lead target was then replaced with tungsten and tungsten-copper and the simulations repeated. The calculated heat generation rates for the tungsten and tungsten-copper targets in BP#5 are shown in Tables III and IV, respectively. The heat generation rates obtained at $k_{eff}=0.99$ for both targets are sufficient for obtaining the desired negative fuel temperature feedback; however, again the system cannot be operated at lower k_{eff} values. It was noted that the tungsten targets were sufficiently superior to the lead target but that the two tungsten targets were not statistically different in heat generation rates.

TABLE III
Heat Generation Rate for Tungsten Target in BP#5

k_{eff}	Heat Generation Rate (kW)
0.9509 +/- 0.0007	0.46 +/- 0.02
0.9804 +/- 0.0007	1.06 +/- 0.08
0.9903 +/- 0.0007	2.07 +/- 0.165

TABLE IV
Heat Generation Rate for Tungsten-Copper Target in BP#5

k_{eff}	Heat Generation Rate (kW)
0.9510 +/- 0.0006	0.56 +/- 0.02

0.9896 +/- 0.0007	2.15 +/- 0.15

III.B.2. Core Arrangement #2

In this arrangement, the target was placed in the central thimble in the UT-NETL core. The cooling jacket was removed and pool water was used to cool the source. The target had a radius of 3.506 cm and was 25.0 cm long. The stainless steel cladding on the target was 0.574 cm thick. The electron beam entered the target from above. A thin beryllium window (0.001 cm thick) faced the electron beam for the lead target but was removed for the tungsten targets. A stainless steel beam stop of 4 cm in thickness was attached to the end of the target. The top of the target was in parallel with the top of the fuel meat for the fuel elements. A schematic of the target in position is shown in Fig. 10. The MCNP-5 calculated heat generation rates in the fuel for this arrangement and the lead, tungsten, and tungsten-copper targets are shown in Tables V, VI, and VII. As can be seen the results from all of these simulations are the same or lower than those from core arrangement #1. This is due to the high absorption of neutrons by the water between the target and the fuel and by the absorption of neutrons in the control rods.

0.9901 +/- 0.0007	1.88 +/- 0.17

III.B.3. Core Arrangement #3

The target radius was re-optimized by varying its radius while inside the core and noting the heat generation rate. It was found that a larger target radius produced significantly more heat in the fuel. This is due primarily to the displacement of water between the target and the fuel. An optimized target radius of 4.206 cm was found with a stainless steel cladding thickness of 0.574 cm. Also to decrease absorption of source

neutrons in the control rods, the control rods were moved one ring out away from the target. Core arrangement #3 is shown in Fig. 11. The MCNP-5 calculated heat generation rates in the fuel for this arrangement and the lead, tungsten, and tungsten-copper targets are shown in Tables VIII, IX, and X.

Fig. 11. Screen capture of MCNP geometry for UT-NETL experiment with target at the center of the core and control rods one fuel element away.

TABLE VIII

Heat Generation Rate for Lead Target in Core Arrangement #3

k_{eff}	Heat Generation Rate (kW)
0.9494 +/- 0.0008	0.845 +/- 0.035
0.9800 +/- 0.0008	1.735 +/- 0.115

k_{eff}	Heat Generation Rate (kW)
0.9501 +/- 0.0007	0.63 +/- 0.03
0.9800 +/- 0.0007	1.21 +/- 0.075
0.9903 +/- 0.0006	2.045 +/- 0.15

TABLE X

Heat Generation Rate for Tungsten-Copper Target in Core Arrangement #3

k_{eff}	Heat Generation Rate (kW)
0.9501 +/- 0.0007	1.32 +/- 0.035
0.9805 +/- 0.0007	1.55 +/- 0.115
0.9901 +/- 0.0007	2.37 +/- 0.18

The heat generation rates (especially for the tungsten-copper target) has increased to almost 2.4 kW at $k_{eff}=0.99$. Thus moving the control rods away from the target and increasing the target size resulted in significantly higher heat generation. It should still be noted that the heat generation rate at lower k_{eff} values is still too small to allow for a realistic temperature feedback effect.

III.B.4. Core Arrangement #4

In order to determine if additional movement of the control rods away from the target would increase the system heat generation rates, an additional core arrangement was considered with the control rods moved out another ring from the center. In this case, these analyses were performed only for the tungsten-copper target. The target had a radius of 4.206 cm and a clad thickness 0.574 cm. The target is located such that the top of the target is in parallel with the top of the fuel meat. A schematic of this core arrangement is shown in Fig. 12.

Two additional perturbations to this arrangement were simulated. The target was then moved to two different axial positions: one such that the target top is 4 cm below the top of the fuel meat and the other such that the target top is 8 cm below the top of the fuel meat. All these simulations were performed with a $k_{eff}=0.9900$. The results for these simulations with different target axial locations are shown in Table XI. As can be seen, the heat generation rates from these simulations suggest that this experiment should be able to reach well within the temperature feedback regime.

Fig. 12. Screen capture of MCNP geometry for UT–NETL experiment with target along with jacket at the center of the core and rods two fuel element away.

TABLE XI

Heat Generation Rate for Tungsten-Copper Target in Core Arrangement #4 with the Target Located at Different Axial Heights

Target Axial Location	Heat Generation Rate (kW)
in parallel with fuel meat	3.05 +/- 0.295
4 cm below fuel meat	3.475 +/- 0.21
8 cm below fuel meat	5.055 +/- 0.35

A set of simulations were also performed to analyze the effect of removing the cladding from the target. Again the tungsten-copper target was considered. One simulation considered simply removing the cladding. The other simulation considered removing the cladding and increasing the radius of the target. Schematics showing the target arrangement for these three simulations can be found in Fig. 13. In all cases the target was placed at 8 cm below the top of the fuel meat. The heat generation results for these three arrangements can be found in Table XII. As can be seen the target produces more heat with the cladding in place. This is due to the higher neutron absorption in the tungsten than in the stainless steel. Thus, it is preferred to retain the stainless steel cladding as a means for displacing water in the core.

Fig. 13. Screen capture of MCNP geometry for UT–NETL experiment with accelerator source target at core center with (a) cladding, (b) no cladding, and (c) no cladding and larger radius.

TABLE XII
Heat Generation Rate for Tungsten-Copper Target in Core Arrangement #4 with the
Target Located at Different Axial Heights

Target Axial Location	Heat Generation Rate (kW)
cladding	5.055 +/- 0.35
no cladding	4.44 +/- 0.20
no cladding and larger radius	4.45 +/- 0.225

III.C. Optimal Core Configuration for UT-NETL RACE

The optimized core configuration for the RACE experiments at the UT-NETL was determined based on the results from Section III.B. The optimal configuration consisted of the following:

1. Tungsten-copper target with a radius of 4.206 cm surrounded by a stainless steel cladding with a thickness of 0.574 cm.
2. The target located in the central thimble and 8 cm below the top of the fuel meat.
3. A 4-cm thick stainless steel beam stop included at the bottom of the target.
4. The control rods moved out two rings from the standard operating position.
5. The outer ring of the core occupied by graphite dummy elements.

An axial schematic of this core arrangement is shown in Fig. 14. A radial schematic of this core arrangement is shown in Fig. 12.

Fig. 14. Screen capture of axial view of the final design MCNP geometry for UT–NETL reactor accelerated coupled experiment.

Analysis of this optimized core arrangement was performed to allow for a better understanding of the expected experimental results. Plots of the k_{eff} versus rod position, heat generation rate versus rod position, and heat generation rate versus k_{eff} are shown in Figs. 15, 16, and 17, respectively.

Fig. 15. k_{eff} versus control rod positions.

Fig. 16. Heat generation versus rod position.

Fig. 17. Heat generation versus k_{eff} .

At the highest rod position, the bottom of the absorber is parallel to the top of the fuel meat. At the lowest rod position, the fuel follower is parallel to the bottom of the fuel element. As can be seen, k_{eff} can be varied from 0.975 to 0.999 and still produce over 3 kW of heat. This should provide flexibility to operate at wide range of subcriticality levels while still within the feedback regime. It should also be noted that with the target in place and rods fully withdrawn the system is still not critical though it is close. From these calculations, it has been shown that the RACE experiments using the UT-NETL core should provide a feasible mechanism for achieving an ADS experiment with temperature feedback over a wide range of subcriticality levels.

IV. TEXAS TRANSMUTATION SYSTEM DESIGN

One interest in the RACE program is in producing a permanent facility for studying ADS characteristics and to serve as an educational and training tool for ADS operation. A subcritical assembly composed of spent fuel discharged from the TAMU NSC TRIGA reactor will be designed and built for location in the NSC pool to serve this goal. The TRIGA reactor at TAMU has been in operation since 1961. Present at the facility is a complete core load of spent fuel. This spent fuel will be assembled into a subcritical lattice (within the existing NSC pool) with four internal accelerator driven target positions and three safety control rods. The system will be designed such that it will remain subcritical with the control rods completely removed from the core. Thus, the control rods only serve as shutdown safety rods, but can also be used to operate the system at lower levels of subcriticality as well. This experimental system will allow for evaluation of the ADS with the accelerator source in different locations in the core. The system will also serve as a teaching tool since its design maintains the system in a subcritical configuration and thus is more “student-friendly”. This design has been named the Texas Transmutation System (TTS).

IV.A. History of TAMU NSC Reactor

The Nuclear Science Center Reactor (NSCR) operated from 1962 until 1967 with MTR-type curved aluminum plate elements. During this time the reactor was operated extensively at a maximum power level of 100 KW. In 1968, the reactor was converted to

General Atomic TRIGA type fuel rods and the maximum power level was increased to 1.0 MW. The initial core loading produced satisfactory operation, but the experimental facility was soon affected by both fuel burnup and samarium buildup. To restore excess reactivity, additional fuel was periodically added to the core and a graphite reflector was added to all four surfaces. This eventually led to 126 element core with a resultant decrease in flux of almost 40% and the elimination of most of the irradiation facilities.

In August, 1970, fuel followed rods were installed to help solve the problem of maintaining excess reactivity. This installation required modification of the grid plate to allow passage of the fueled portion of the control rod through the grid plate. An average reactivity increase of \$ 1.10 per fueled follower was achieved which extended the core life by nearly two years. The high burnup rate of standard TRIGA cores continued to be an operational problem for the NSCR which operated at a burnup of approximately 100 MW-days per year since 1969.

General Atomic FLIP (Fuel Life Improvement Program) fuel was designed to replace standard TRIGA fuel elements. FLIP fuel has the same dimensions as standard TRIGA fuel and differs only in material composition. The enrichment was increased from 20% to 70%, the hydrogen to zirconium ratio was decreased from approximately 1.7 to 1.6, and 1.5 weight percent natural erbium was added as burnable poison. FLIP fuel has an expected lifetime of 9 MW-years which is considerably higher than the $\frac{1}{2}$ MW-year lifetime of standard fuel.

Since funds were not available for a complete FLIP core, the initial core operated with a mixture of FLIP and standard TRIGA fuel. A precedent for this had been established by General Atomic when they operated a standard core loaded with eighteen centrally located FLIP elements in a fuel test program. Calculations were performed at Texas A&M which led to the conclusion that satisfactory core arrangements were possible with a mixed core. The NSCR operated with two mixed core loadings containing 35 FLIP elements and 59 FLIP elements each between 1973 and 1979. As funds became available, the amount of FLIP fuel was increased until a complete FLIP loading was achieved.

By 1979, all standard fuel had been replaced and cores V-VIII were operated with FLIP fuel only. From 1979 to the present, the maximum power level has remained at 1.0 MW.

IV.B. TTS Design Concept

TTS is a multi-target sub-critical assembly of standard TRIGA fuel driven by an electron accelerator. This system will make use of the complete core load of spent fuel available at the NSC. This spent fuel will be assembled into a subcritical lattice (within the existing NSC pool) with four internal accelerator driven target positions and three safety control rods (Fig. 18). The system will be designed such that it will remain subcritical with the control rods completely removed from the core. Thus, the control rods only serve as shutdown safety rods, but can also be used to operate the system at lower levels of subcriticality as well.

Fig. 18. MCNP geometry of TTS TAMU with four target positions

TABLE XIII
Heat Generation Rate for TTS Design

k_{eff}	Heat Generation Rate (kW)
0.942 +/- 0.001	5.37 +/- 0.18

MCNP simulations were performed to evaluate the initial TTS design. A copy of the TTS input deck can be found in Appendix C. The system was modeled explicitly and a 40-MeV, 100- μ A electron beam was impacted on the center of all the targets in the design. The heat generation rate in the fuel was then tallied. There are in total 120 standard fuel elements in a close packing in the TTS. The fuel isotopics was calculated

using a two-dimensional HELIOS calculation for the NSC TRIGA reactor. The isotopics included in MCNP however only included the decrease in actinide content due to burnup and all fission products were included as one average fission product in MCNP. In future efforts for designing TTS, a more detailed fuel mixture will be used. The result for the calculated heat generation rate for TTS is shown in Table XIII. As can be seen, even with a low level of subcriticality, the TTS system produces sufficient heat to allow for operation in the temperature feedback regime for TRIGA reactor fuel.

IV.C. TTS Evaluation Results

In addition to the total heat generation rate shown in Table XIII, heat generation rates in individual elements in TTS were tallied to show the spatial distribution of heat production. Specifically, the interest was in determining that there were not any particular rods that were subjected to a heat load beyond the design basis for TRIGA fuel (which is approximately 35 kW per fuel element). Also, heat generation rates in the targets were tallied to determine the heat load on the targets. Again, the targets will be cooled by natural circulation in the NSC pool and the heat loads on the targets must remain below the fuel element design basis to ensure appropriate cooling. The heat generated in each of the elements is due to three sources: (1) non-fission neutron reactions (mainly elastic and inelastic scattering), (2) neutron-induced fission reactions, and (3) photon reactions. For tallying these results, $f7:n$ and $f6:p$ tallies in MCNP-5 were used. It should be noted that energy deposition due to electron slowing down was not tallied; however, it is assumed that almost all of the power from the accelerator beam (4

kW) will be deposited locally as heat in the target. The heat deposition in the targets for neutron reactions, photon reactions, and all neutron and photon reactions is shown in Figs 19, 20, and 21, respectively. As can be seen the heat deposition in the target is well below the single element limits for the system and this energy deposition is due almost entirely to photon energy deposition.

Fig. 19. Heat generation in the four targets due to neutron reactions.

Fig. 20. Heat production in the four targets due to photon reactions.

Fig. 21. Total heat production in the four targets.

The heat deposition in the fuel elements for neutron reactions, photon reactions, and all neutron and photon reactions total is shown in Figs 22, 23, and 24, respectively. Again it can be seen that the heat deposition in any single element is well below the limits for TRIGA reactor fuel. Thus, cooling concerns for this system should be insignificant.

Fig. 22. Heat generation rate in fuel due to neutron reactions.

Fig. 23. Heat generation rate in the fuel due to photon reactions.

Fig. 24. Total heat generation rate in fuel.

It has been shown that the heating rates in the TTS are expected to provide sufficient temperature in the fuel to produce measurable temperature feedback effects. This will allow for transient and steady-state studies of ADS operation under feedback conditions. These experiments will be used to provide benchmark data for development of ADS code systems.

V. CONCLUSIONS

The objective of this feasibility study was to aid in the development of subcritical accelerator driven systems with feedback. The current operational and experimental experience with such systems is effectively non-existent. These experiments will provide the first dataset for such conditions.

Design of a tungsten-copper target for the production of neutrons from a 40 MeV, 100 μ A electron accelerator was performed. The optimized target geometry was found to be that of a right circular cylinder with a radius of 3.2 cm and a length of 25 cm. This target will produce a neutron source of approximately 10^{12} neutrons per second. It should be noted that for this accelerator driven target, the neutron source strength is relatively insensitive to the radius and length of the target. This allows for more flexibility in altering the target dimensions to allow for incorporation in different ADS configurations.

For the purposes of observing temperature feedback in the RACE systems, heat generation rates for the total systems were needed to be above 1 kW and preferably above 5 kW. All simulations used a 40-MeV, 100- μ A accelerator beam. It was shown that with this accelerator the configuration #4 for the UT-NETL reactor using a tungsten-copper target will provide 5.05 kW of heat generation with a $k_{eff}=0.99$ and 1.25 kW of heat generation with a $k_{eff}=0.95$. This will provide sufficient heat for temperature feedback operation over a wide range of subcriticality levels.

The overheating of the target may determine the limit for the maximum current of the accelerator and thus the total heat generation in the system. To compensate for this limitation, a multi-target system named the TTS was analyzed. It was shown that the TTS system would provide excellent heat production over a wide range of subcriticality levels and could serve as a permanent experimental system for teaching and training the next generation of nuclear scientists and engineers.

Operationally, the RACE program is intended to consist of a number of experiments which will be used as benchmarks for steady-state and transient operation of ADS. It has been shown that with modest accelerator capabilities, two experiments could be performed which would allow for operation in a temperature feedback regime. It is the recommendation of this thesis that the experiments begin with beam port experiments (core arrangement #1 from Section III) using a cooling jacket. This will provide for low power experiments that could be performed over a wide range of subcriticalities without any impact on normal reactor configuration or operation. Following these experiments, the target would be moved internal to the reactor (core configuration #4 from Section III) and experiments would be performed that would be well within the temperature feedback regime of the TRIGA fuel. Following this experiments could be performed with the TTS arrangement at TAMU and allow for a wider range of experiments over a longer time period (since this would not impact reactor operation in any way). Finally, it should be noted that if a higher current accelerator system could be acquired (for example a 25 kW accelerator similar to

industrial irradiator systems currently in use), then the heat generation rates in these system could well exceed 80-100 kW. These calculations have shown that the feasibility of the RACE program is well within the capabilities of existing systems and arrangements for performing the experiments should proceed accordingly.

APPENDIX C

TTS MCNP Input Deck

```

Initial TTS Core Design
c
c
c ---- Description: ----
c
c      This deck simulates a full-core subcritical design using
c      TRIGA reactor fuel and an accelerator driven neutron source.
c      The accelerator source is a 40-MeV electron accelerator.
c      This beam impinges normal to a lead target in the center of
c      the core. The electrons then create an intense gamma-ray
c      source which in turn generates a photoneutron source. The
c      complete deck requires long run times because only ~1 neutron
c      is created for every 100 electrons input.

c - source definition
c
c (There are two sources here. One is a criticality source using a

```

```

c      single initial source position.  The other is a electron beam
c      source positioned on the central target.  To move the electron
c      beam source to the other targets we simply change the position
c      parameter on sdef.  The electron beam source takes a very long
c      time to run.)
